1 Career Concerns

Lets begin by considering the last period. Putting aside the unknown skill, notice that effort is costly, there is no performance pay and there is no future. Therefore workers never exert effort in period 2, so $e_2^* = 0$.

Next, notice that because workers also do not know their own skill, all workers will choose the same level of effort in period 1. (Or they will mix, but we will assume they do not). Firms understand that all workers exert the same effort. For reasons that will become clear, lets denote this effort level \tilde{e}_1 .

Now, firms do not observe effort. But in equilibrium they “understand” that all workers exert \tilde{e}_1 . This understanding is why we denote this effort with a tilde. They also observe revenue. Thus, after period 1 firms can just subtract effort from output to get skill: $y_1 - \tilde{e}_1 = a + \tilde{e}_1 - \tilde{e}_1 = a$.

We need to specify what happens if the firm observes revenue less than \tilde{e}_1 or greater than $\tilde{e}_1 + A$. We will assume for our simple model that firms believe $a = 0$ in the first case and $a = A$ in the second case. The justification is that firms do not become more pessimistic when they see higher revenue and they do not become more optimistic when they see lower revenue. Notice that we need this assumption. Revenue outside $[\tilde{e}_1, \tilde{e}_1 + A]$ is not going to occur in equilibrium but the worker will still consider choosing a very different effort level that could make it possible. These are “global deviations.”

In this way, in period 2 skill is known. The firms then compete Bertrand style for the worker. They know skill is a and they know $e_2^* = 0$, so revenue from the worker is just skill: $y_2 = a + e_2^* = a$. Both firms bid a wage of $w_2^* = a$. To see why, consider any deviation from this strategy, keeping the other firm bidding at a . If either firm deviates to $w > a$, they win the worker but lose money because $a - w < 0$. Suppose a firm bids a wage below a . Then they lose for sure and still get 0.

Now consider the worker’s choice of effort in period 1. The period 1 wage w_1 is already decided by this point and it is a flat wage, so it does not impact the worker’s choice of effort. When finding the worker’s effort choice in period 1, we must be careful, because there are two efforts floating around. There is actual effort e_1 , which the worker controls and the firm does not see, and there is \tilde{e}_1 , the effort the firm expects the worker to put in. The worker can make the firm think that he/she is higher skill by exerting effort that is different than \tilde{e}_1 . But the worker CANNOT impact the firm’s belief about effort \tilde{e}_1 . Thus when we take derivatives to find e_1 , the effort the firm thinks will happen, \tilde{e}_1 , will behave as a constant.

This is the heart of the model: the worker has an incentive to work harder to build a better reputation. The worker’s payoff from effort in period 1 is the flat wage in period 1 and 2 less the cost of effort in both periods. Remember, the effort in period 2 is always 0 which has no cost. Importantly, the period two wage is impacted by period 1 effort, because this determines what the market thinks about the worker’s skill. Thus the worker maximizes:

$$\max_{e_1} w_1 + E[w_2(e_1, \tilde{e}_1)] - e_1^2/2$$

The expected wage in period 2 given effort e_1 and expected effort \tilde{e}_1 is:

$$E[w_2(e_1, \tilde{e}_1)] = E[y_1 - \tilde{e}_1] = E[a + e_1 - \tilde{e}_1] = E[a] + e_1 - \tilde{e}_1$$

Thus the maximization problem becomes:

$$\max_{e_1} w_1 + E[a] + e_1 - \tilde{e}_1 - e_1^2/2$$

assuming e_1 is in the range $(\tilde{e}_1, \tilde{e}_1 + A)$. Taking derivative with respect to only e_1 (not \tilde{e}_1):¹

$$[e_1] : 1 - e_1 = 0 \leftrightarrow e_1^* = 1$$

In equilibrium, the market's belief must match reality, so $\tilde{e}_1 = e_1^* = 1$. Notice that this is the first-best level of effort because it is equating the marginal cost of effort to the marginal benefit of effort. So career concerns motivate the worker to provide the efficient amount of effort!

The last piece to recover is the period 1 wage. At this point, no one knows true skill a . So the value to the firms of the worker in period 1 is just expected skill plus the effort everyone exerts in period 1: $e_1 = \tilde{e}_1 = 1$. By the same argument we used in period 2, firms bid exactly $E[a] + \tilde{e}_1$. The mean of a uniform random variable is just the middle of the range: $(A + 0)/2$ so the wage in period 1 will be $w_1^* = A/2 + \tilde{e}_1 = A/2 + 1$.

It turns out that there are some technical conditions we need to get these results. One condition that assures everything "works" is that A is sufficiently large.

2 Wages

Suppose $A = 10$. Then wage in the first period is $A/2 + 1 = 6$. Workers are distributed uniformly between $[0, 10]$. Wage in the second period is a . Thus for the 60% of workers with skill $a < 6$ wages go down over time, while for the 40% of workers with skill $a > 6$ wages go up.
